Realized Beta GARCH:
A Multivariate GARCH Model with Realized Measures of Volatility*

Abstract

We introduce a multivariate GARCH model that incorporates realized measures of variances and covariances. Realized measures extract information about the current levels of volatilities and correlations from high-frequency data, which is particularly useful for modeling financial returns during periods of rapid changes in the underlying covariance structure. When applied to market returns in conjunction with returns on an individual asset, the model yields a dynamic model specification of the conditional regression coefficient that is known as the \textit{beta}. We apply the model to a large set of assets and find the conditional betas to be far more variable than usually found with rolling-window regressions based exclusively on daily returns. In the empirical part of the paper, we examine the cross-sectional as well as the time variation of the conditional beta series during the financial crises.

1 Introduction

Relatively accurate measurements of volatility and covariances can be computed from high frequency data, and such statistics are commonly referred to as realized measures. Incorporating realized measures when modeling the dynamic properties of volatility is very beneficial, and leads to better empirical fit than conventional GARCH models, which only use daily returns. The reason is that returns yield very weak signals about latent volatility, whereas realized measures provide accurate measurements. The latter is particularly useful during times of rapid changes in volatility and correlations.

In this paper we propose a multivariate GARCH-type model that utilizes and models realized measures of volatility and correlations. The model has a hierarchical structure where the “market” return is modeled with a univariate Realized GARCH model, see Hansen and Huang (2012) and Hansen et al. (2012). A multivariate structure is constructed by modeling “individual” returns conditional on the past and contemporary market variables (return and volatility). The resulting model has the structure of a dynamic CAPM model that enables us to extract the “betas” and study their dynamic properties. Moreover, the model is complete in the sense that all observables (returns, realized volatilities and realized correlations) are modeled. The latter enables us to infer the distribution of multi-period returns including the joint distribution of “market” returns and “individual” returns over longer horizons.

The main contributions of our paper are the following. We propose a flexible and tractable framework that enables the modeling of a potentially large set of assets. Unlike conventional multivariate GARCH models, which can suffer from the curse of dimensionality and estimation issues, we avoid such issues by incorporating realized measures and the use of measurement equations. The measurement equations tie realized measures to latent volatilities and correlations, and this leads to a useful regularization of the model. This particular structure was chosen for a number of reasons. First, the model provides good empirical fit for the wide range of assets used in our empirical study; Second, the structure of the model is amenable to a deeper analysis of secondary quantities such as betas; Third, the model is simple to estimate, which is particularly important when a large set of assets are to be analyzed as is the case in our empirical analysis.

The proposed model has a hierarchical structure where the market return and a correspond-
ing realized measure form the core of the model. The model can be extended to an arbitrarily large set of individual returns, by adding a conditional model for an individual return and two realized measures, one being a realized measure of return volatility, the other being a realized measure of the correlation between the individual return and the market. This yields a flexible model with a dynamic covariance structure that is constantly revised by using the information contained in the realized measures.

The concept of realized betas is not new. Bollerslev and Zhang (2003) carry out a large scale estimation of the Fama-French three-factor model using high-frequency (5-minute) data on 6,400 stocks over a period of 7 years. Their analysis showed that high-frequency data can improve the pricing accuracy of asset pricing models. Their approach differs from ours in important ways. For instance, they model raw realized factor loadings and use simple time series processes to forecast these. So there is no explicit link between realized and conditional moments of returns in their framework. Nor do they explicitly account for the measurement error (the sampling error) in the realized quantities. Another related paper is Andersen et al. (2006) who study the time variation in realized variances, covariances, and betas using daily returns to construct quarterly realized measures. They find evidence of long memory in the time series for variance and covariances, while the realized beta time series is less persistent and seemingly a short-memory process, which is indicative of fractional cointegration between realized volatility and realized covariance. Other related studies include: Barndorff-Nielsen and Shephard (2004a) who established asymptotic results for realized beta, and Dovonon et al. (2013) who established the theory for bootstrap inference. MSE-optimal estimation of realized betas was analyzed in Bandi and Russell (2005), and Patton and Verardo (2012) studied the impact of news on betas. Morana (2009) uses realized betas to explain the variation in expected returns, and Corradi et al. (2011) use realized betas to extract the conditional “alphas”. The importance of separating jump and continuous components of returns in relation to betas, as highlighted in Todorov and Bollerslev (2010), and Tsay and Yeh (2011), allow the dynamic beta to vary within the day.

The use of realized volatility measures in this context yields valuable insight about the degree of time-variation in the betas, which has been up for debate in the literature. The studies by Ferson and Harvey (1991, 1993), and Shanken (1990) specify parametric relationships between betas and proxies for the state of the economy and find support for time-varying betas. Gomes et al. (2003) provide a theoretical justification for a time-varying conditional beta specification in the context of a dynamic general equilibrium production economy. Conditional betas have
been modeled by means of conventional GARCH models by Braun et al. (1995) and Bekaert and Wu (2000), among others. Lewellen and Nagel (2006) argue that variation in betas would have to be “implausibly large” to explain important asset-pricing anomalies. In our empirical analysis we do find a substantial amount of time-variation in the conditional betas. This is in particular the case during the global financial crises period. We find the variation in betas to be substantial, even over short periods of time, such as a quarter.

The research devoted to high-frequency volatility measures was spurred by Andersen and Bollerslev (1998), who documented that the sum of squared intraday returns, known as the realized variance, provides an accurate measurement of daily volatility. The theoretical foundation of realized variance was developed in Andersen, Bollerslev, Diebold and Labys (2001) and Barndorff-Nielsen and Shephard (2002). A large number of related estimators, such as realized bipower variation, realized kernels, multi-scale estimators, preaveraging estimators and Markov chain estimators have been proposed to deal with issues such as jumps and market microstructure frictions, see Barndorff-Nielsen and Shephard (2004b), Barndorff-Nielsen, Hansen, Lunde and Shephard (2008), Zhang (2006), Jacod et al. (2009), Hansen and Horel (2009) and references therein. The multivariate extensions of the concept of realized volatility is theoretically developed in Barndorff-Nielsen and Shephard (2004a). Estimators that are robust to noise and/or asynchronous observations have been proposed by Hayashi and Yoshida (2005), Voev and Lunde (2007), Griffin and Oomen (2011), Christensen et al. (2010), and Barndorff-Nielsen et al. (2011). In this paper we will rely on the multivariate kernel estimator by Barndorff-Nielsen, Hansen, Lunde and Shephard (2011) that guarantees positive semi-definite estimates of the realized variance-covariance matrices.

While volatility is unobservable, the use of realized measures allows us to construct precise ex-post volatility proxies. Currently, a growing body of research investigates the extend to which realized measures can be used to improve the accuracy of volatility forecasts. Hansen and Lunde (2010) categorize the existing approaches into two broad classes: reduced-form and model-based. Reduced-form volatility forecasts are based on a time series model for the series of realized measures, while a model-based forecast rests on a parametric model for the return distribution. Model-based approaches effectively build on GARCH models in which a realized measure is included as an exogenous variable in the GARCH equation, see e.g. Engle (2002b). A complete framework that jointly specifies models for returns and realized measures of volatility was first proposed by Engle and Gallo (2006), who refer to their model as the Multiplicative
Error Model (MEM). A simplified MEM structure was proposed in Shephard and Sheppard (2010), who referred to their model as the HEAVY model. The realized GARCH model by Hansen et al. (2012) involves a different approach to the joint modeling of returns and realized volatility measures. A key component of the Realized GARCH model is a measurement equation that relates the realized measure to the underlying conditional variance. This idea is generalized to a multivariate framework in this paper, where we introduce measurement equations for the realized measures of correlations.

The rest of the paper is structured as follows. The model and the underlying theory is presented in Section 2, and we discuss estimation of the model in Section 3. In section 4 we show how multi-step predictions of volatilities and correlations as well as forecasts of return densities can be obtained from the model. Section 5 contains an empirical application of the model, and Section 6 concludes. Detailed information about the data construction, and auxiliary results that are useful for the estimation are presented in two appendices.

2 A Hierarchical Realized GARCH Framework

Broadly speaking, our objective is the same as that of existing multivariate GARCH models, which is to model the conditional distribution of a vector of returns. But unlike conventional GARCH models we also model the realized measures of volatility and correlation and make extensive use of these in the modeling of returns. The realized measures are highly informative about local (in time) levels of volatility and correlation. By tying all individual return series to the market return, we are implicitly imposing a factor structure on the volatility, where the variation in the correlation structure is driven by time-variation in the correlations between the market return and the individual assets. This keeps the model relatively simple and parsimonious, facilitates estimation, and makes it easy to relate key variables in the model to dynamic betas.

Our model has a hierarchical structure. The core of our framework is a marginal model for the market return and its realized measure of volatility. Individual returns, their realized measures of volatility and correlation (with the market) are then modeled conditionally on market variables. The marginal model we use for the market-specific time series is a reparameterized version of the Realized EGARCH model by Hansen and Huang (2012), see also Hansen et al. (2012, section 6.3), which shares certain features with the EGARCH model by Nelson (1991). The conditional model we use in this paper is new.
Initially, we present the Realized Beta GARCH model in the simplest situation with a bivariate vector of returns (the market return and an individual asset return) and the corresponding $2 \times 2$ matrix of realized volatility measures. Subsequently, we discuss the straightforward extension to an arbitrary number of individual assets.

2.1 Notation and Modeling Strategy

Let $r_{0,t}$ and $x_{0,t}$ denote the market return and a corresponding realized measure of volatility, respectively. Similarly, we use the notation $r_{1,t}$ and $x_{1,t}$ for the same variables associated with an individual asset return, and use $y_{1,t}$ to denote a realized measure of correlation, where $y_{1,t} \in (-1, 1)$.

In this context with two returns, two realized measures of volatility, and a realized measure of correlation we have five observable variables to model. The natural filtration is given by

$$F_t = \sigma(X_t, X_{t-1}, \ldots) \quad \text{with} \quad X_t = (r_{0,t}, r_{1,t}, x_{0,t}, x_{1,t}, y_{1,t})',$$

and we define the conditional variances, $h_{0,t} = \text{var}(r_{0,t}|F_{t-1})$ and $h_{1,t} = \text{var}(r_{1,t}|F_{t-1})$, much like in standard GARCH models, the key difference being that the information set, $F_t$, is richer in the present framework. We also define the conditional correlation, $\rho_{1,t} = \text{corr}(r_{0,t}, r_{1,t}|F_{t-1})$, and it follows directly that the “beta”,

$$\beta_{1,t} = \frac{\text{cov}(r_{1,t}, r_{0,t}|F_{t-1})}{\text{var}(r_{0,t}|F_{t-1})},$$

is given by $\beta_{1,t} = \rho_{1,t} \sqrt{h_{1,t}} / h_{0,t}$. This establishes a connection to a dynamic CAPM and we are particularly interested in the dynamic properties of $\beta_{1,t}$.

The structure of our model will take advantage of the simple decomposition of the conditional density,

$$f(r_{0,t}, x_{0,t}, r_{1,t}, x_{1,t}, y_{1,t}|F_{t-1}) = f(r_{0,t}, x_{0,t}|F_{t-1})f(r_{1,t}, x_{1,t}, y_{1,t}|r_{0,t}, x_{0,t}, F_{t-1}),$$

which serves to illustrate the hierarchical structure of our model. We will adopt the Realized EGARCH model as our specification of the first term, $f(r_{0,t}, x_{0,t}|F_{t-1})$. The specification for the second conditional density, $f(r_{1,t}, x_{1,t}, y_{1,t}|r_{0,t}, x_{0,t}, F_{t-1})$, defines how the time series associated with the individual asset evolves conditional on contemporary market variables. Our specification of this conditional density has a structure that is similar to that of the univariate Realized
GARCH model, but has some important adaptations for the modeling of the correlation structure. Realized correlation measures between the individual assets are not needed, because it is implicitly assumed that these correlations are characterized through the correlations between the individual returns and the market return. In our empirical analysis, we investigate the validity of this assumption.

2.2 Realized EGARCH Model for Market Returns

The Realized EGARCH model for market returns and realized measures of volatility is given by the following three equations

\[
\begin{align*}
\tau_{0,t} &= \mu_0 + \sqrt{h_{0,t}}z_{0,t}, \\
\log h_{0,t} &= a_0 + b_0 \log h_{0,t-1} + c_0 \log x_{0,t-1} + \tau_0(z_{0,t-1}) \\
\log x_{0,t} &= \xi_0 + \varphi_0 \log h_{0,t} + \delta_0(z_{0,t}) + u_{0,t}.
\end{align*}
\]

Here, we do not follow the conventional GARCH notation, because we want to reserve the notation “\(\beta\)” for the market-beta variable we defined in (1).

In our likelihood analysis we specify \(z_{0,t} \sim \text{iid} \mathcal{N}(0, 1)\) and \(u_{0,t} \sim \text{iid} \mathcal{N}(0, \sigma^2_{u_0})\). The properties of the estimators do not critically hinge on this Gaussian specification being correct. Still, the Gaussian specification for \(u_{0,t}\) can be motivated by findings in Andersen, Bollerslev, Diebold and Labys (2001), Andersen, Bollerslev, Diebold and Ebens (2001) and Andersen et al. (2003), who document that realized volatility is approximately log-normal. Furthermore, Andersen, Bollerslev, Diebold and Ebens (2001) find that returns standardized by realized volatility are approximately normally distributed.

The functions \(\tau(z)\) and \(\delta(z)\) are called leverage functions because they model aspects related to the leverage effect, which refers to the dependence between returns and volatility. Hansen et al. (2012) found that a simple second-order polynomial provides a good empirical fit. We will adopt this structure in our framework, and set \(\tau(z) = \tau_1 z + \tau_2(z^2 - 1)\) and \(\delta(z) = \delta_1 z + \delta_2(z^2 - 1)\). This leads to a GARCH equation that is somewhat similar to that of an EGARCH model. But unlike the EGARCH model, we also utilize the realized measure, \(x_{0,t-1}\), to model the dynamics of volatility.

We refer to the first two equations, (3) and (4), as the return equation and the GARCH equation, respectively. These two equations define a GARCH-X model, similar to those esti-
mated by Engle (2002, b), Barndorff-Nielsen and Shephard (2007), and Visser (2011). See also Chen et al. (2011) for additional variants of the GARCH-X model and some related models.

The third equation, (5), called the measurement equation, completes the specification of the density, \( f(r_{0,t}, x_{0,t}|\mathcal{F}_{t-1}) \). Tying the realized measure, \( x_t \), to the conditional variance, \( h_t \), is motivated by the fact that the GARCH equation trivially implies that

\[
\log(r_t - \mu)^2 = \log h_t + \log z_t^2.
\]

Since the realized measure, \( x_t \), is similar to \( r_t^2 \) in the sense of being a measurement of volatility (just far more accurate), it is natural to expect that \( \log x_t \approx \log h_t + g(z_t) + \text{error}_t \), for some function \( g \). Because we may compute realized measures of volatility over a shorter period of time than the one spanned by the return (e.g., if we use only data from the trading session, which often excludes the overnight period), some flexibility in the specification may be required motivating the “intercept” \( \xi_0 \) and the “slope” \( \varphi_0 \). So long as \( x_{0,t} \) is roughly proportional to \( h_{0,t} \), we should expect \( \varphi_0 \approx 1 \), and \( \xi_0 < 0 \), which is always the case empirically.

### 2.3 Conditional Model for An Individual Asset Return and Its Realized Measures

To extend the framework to a joint model for the market returns/volatility and another asset’s return/volatility and their correlation, we shall formulate a model for the time series associated with the individual asset, conditional on contemporaneous “market” variables, i.e., a specification for \( f(r_{1,t}, x_{1,t}, y_{1,t}|r_{0,t}, x_{0,t}, \mathcal{F}_{t-1}) \). We utilize a further decomposition of this conditional density, specifically

\[
f(r_{1,t}, x_{1,t}, y_{1,t}|r_{0,t}, x_{0,t}, \mathcal{F}_{t-1}) = f(r_{1,t}|r_{0,t}, x_{0,t}, \mathcal{F}_{t-1})f(x_{1,t}|r_{1,t}, r_{0,t}, x_{0,t}, \mathcal{F}_{t-1}).
\]

The first part, \( f(r_{1,t}|r_{0,t}, x_{0,t}, \mathcal{F}_{t-1}) \), is modeled with

\[
r_{1,t} = \mu_1 + \sqrt{h_{1,t}} z_{1,t}, \tag{6}
\]
where the dependence on \((r_{0,t}, x_{0,t})\) operates through the conditional correlation, \(\rho_{1,t} = \text{cov}(z_{0,t}, z_{1,t}|\mathcal{F}_{t-1})\). This reveals the “factor” structure, since we have,

\[
z_{1,t} = \rho_{1,t} z_{0,t} + \sqrt{1 - \rho_{1,t}^2} w_{1,t},
\]

where \(w_{1,t} = (z_{1,t} - \rho_{1,t} z_{0,t})/\sqrt{1 - \rho_{1,t}^2}\), has mean zero, unit variance, and is uncorrelated with \(z_{0,t}\). Hence, the studentized returns for the individual asset is a linear combination of the studentized market return and the idiosyncratic component \(w_{1,t}\), where the relative weighting (defined by \(\rho_{1,t}\)) is time varying.

To complete this part of the model, we need to specify the dynamics for \(h_{1,t}\) and \(\rho_{1,t}\). For \(h_{1,t}\) we use the GARCH equation,

\[
\log h_{1,t} = a_1 + b_1 \log h_{1,t-1} + c_1 \log x_{1,t-1} + d_1 \log h_{0,t} + \tau_1(z_{1,t-1}), \tag{7}
\]

which only differs from (4) by the presence of the term, \(d_1 \log h_{0,t}\). Recall that \(h_{0,t}\) is \(\mathcal{F}_{t-1}\)-measurable, so that the presence of \(h_{0,t}\) on the right hand side does not contradict our definition of \(h_{1,t}\). The parameter \(d_1\) can be interpreted as a spillover effect that measures the extend to which the market’s volatility affects the volatility of the individual asset while accounting for the asset-specific volatility dynamics.

For the dynamic modeling of \(\rho_{1,t}\) we shall use of the Fisher transformation (also known as the inverse hyperbolic tangent, \(\text{arctanh}\)), \(\rho \mapsto F(\rho) \equiv \frac{1}{2} \log \frac{1+\rho}{1-\rho}\), which is a one-to-one mapping from \((-1, 1)\) into \(\mathbb{R}\). The GARCH equation for the transformed correlations is given by

\[
F(\rho_{1,t}) = a_{10} + b_{10} F(\rho_{1,t-1}) + c_{10} F(y_{1,t-1}).
\]

Finally, to specify the conditional density for the last two realized measures, \(f(x_{1,t}, y_{1,t}|r_{1,t}, r_{0,t}, x_{0,t}, \mathcal{F}_{t-1})\), we use the measurement equations,

\[
\begin{align*}
\log x_{1,t} &= \xi_1 + \varphi_1 \log h_{1,t} + \delta_1(z_{1,t}) + u_{1,t}, \tag{8} \\
F(y_{1,t}) &= \xi_{10} + \varphi_{10} F(\rho_{1,t}) + v_{1,t}. \tag{9}
\end{align*}
\]

These measurement errors will be assumed to be independent of \((z_{0,t}, z_{1,t})\), implying that the conditioning on \((r_{1,t}, r_{0,t})\) is captured by \(\delta_1(z_{1,t})\). The three measurement errors are allowed to be correlated. and we define their covariance matrix,
We find significant correlation across all measurement errors in our empirical application.

2.4 The Extensions to Multiple Individual Assets

We have specified the model structure for a market return and a single individual asset (along with their corresponding realized volatility variables). Next, we discuss the extension to multiple assets. Fortunately, the existing structure is amendable to this extension, albeit some additional assumptions are needed before certain interpretations carry over to the general context. First, we need to redefine the natural filtration, \( \mathcal{F}_t = \sigma(\mathcal{X}_t, \mathcal{X}_{t-1}, \ldots) \), to be defined by the full set of variables,

\[
\mathcal{X}_t = (r_{0,t}, r_{1,t}, \ldots, r_{N,t}, x_{0,t}, x_{1,t}, \ldots, x_{N,t}y_{1,t}, \ldots, y_{N,t})',
\]

where \( N \) is the number of individual assets in our analysis. The conditional model for the individual asset is assumed to be invariant to this enhancement of the information set. This implicitly assumes that the dynamic variation in correlations between individual assets is fully explained by the individual asset’s correlation with the market return. Put differently: The variation in the \((N + 1) \times (N + 1)\) conditional covariance matrix is fully described by the \( N + 1 \) conditional variances and the \( N \) conditional correlations. This structure has testable implications that we return to in our empirical section.

In practice, the estimation proceeds by first estimating the model for the market data \((r_{0,t}, x_{0,t})\) and then estimating each conditional model for \((r_{i,t}, x_{i,t}, y_{i,t})\) separately for \( i = 1, 2, \ldots, N \). This can be done for a very large number of assets. For instance, in the empirical analysis we estimated the Realized Beta GARCH model for about 600 assets.

For model diagnostics, in particular the validity of the single-factor structure, we define conditional studentized residuals,

\[
\hat{w}_{i,t} = \frac{\hat{z}_{i,t} - \hat{\rho}_{i,t}\hat{z}_{0,t}}{\sqrt{1 - \hat{\rho}_{i,t}^2}}, \quad i = 1, \ldots, N.
\]

So far the model structure has been silent about the dependence structure across the population equivalents of these residuals, and the same is true for the conditional error terms, \((u_{i,t}, v_{i,t}|u_{0,t})\),
across individual assets. We cast light on this dependence structure in our empirical section.

3 Estimation

In this section, we define the quasi log-likelihood function and exploit its structure to simplify the estimation problem. We have five observed variables, \((r_{0,t}, x_{0,t}, r_{1,t}, x_{1,t}, y_{1,t})\), and we consider their joint density conditional on past information, \(F_{t-1}\). Without loss of generality we can decompose this “joint” density as stated in (2), and, for the purpose of estimation, we adopt Gaussian specifications for the “marginal” and “conditional” densities,

\[
\ell_{z_0} = \sum_{t=1}^{T} \log h_{0,t} + \frac{(r_{0,t} - \mu_0)^2}{h_{0,t}} = \sum_{t=1}^{T} \log h_{0,t} + z_{0,t}^2,
\]

\[
\ell_{u_0} = \sum_{t=1}^{T} \log \sigma_{u_0}^2 + \frac{(\log x_{0,t} - \xi_0 - \varphi_0 \log h_{0,t} - \tau_0(z_{0,t}))^2}{\sigma_{u_0}^2} = \sum_{t=1}^{T} \log \sigma_{u_0}^2 + \frac{u_{0,t}^2}{\sigma_{u_0}^2}.
\]

11
3.2 The Conditional Model for Individual Assets

Next, we consider the likelihood contributions from the conditional model. The conditional model also permits a further decomposition of the conditional density,

\[
f(r_{1,t}, x_{1,t}, y_{1,t}|r_{0,t}, x_{0,t}, F_{t-1}) = f_{r_1|r_0, x_0}(r_{1,t}|r_{0,t}, x_{0,t}, F_{t-1}) \\
\times f_{x_1, y_1|r_1, r_0, x_0}(x_{1,t}, y_{1,t}|r_{1,t}, r_{0,t}, x_{0,t}, F_{t-1}).
\]

The first term is the density of the individual asset’s return conditional on the contemporaneous market variables (and the past). Due to the Gaussian specification we only need to derive the conditional mean and variance of \( r_{1,t} \) in order to compute the appropriate likelihood term. The assumed independence between \( (z_{0,t}, z_{1,t}) \) and \( u_{0,t} \) and the iid assumptions imply that

\[
E(g(r_{1,t})|r_{0,t}, x_{0,t}, F_{t-1}) = E(g(r_{1,t})|z_{0,t}, u_{0,t}, F_{t-1}) = E(g(r_{1,t})|r_{0,t}, F_{t-1}),
\]

for any function \( g \) for which the conditional mean is well defined. Hence,

\[
\text{var}(r_{1,t}|r_{0,t}, x_{0,t}, F_{t-1}) = \text{var}(r_{1,t}|r_{0,t}, F_{t-1}) = h_{1,t} - (\rho_{1,t}\sqrt{h_{0,t}h_{1,t}})^2/h_{0,t} = (1 - \rho_{1,t}^2)h_{1,t},
\]

since \( \text{cov}(r_{1,t}, r_{0,t}|F_{t-1}) = \rho_{1,t}\sqrt{h_{0,t}h_{1,t}}. \) Next, the conditional mean of \( r_{1,t} \) is

\[
E(r_{1,t}|r_{0,t}, x_{0,t}, F_{t-1}) = \mu_1 + \beta_{1,t}(r_{0,t} - \mu_0) = \mu_1 + \frac{\rho_{1,t}\sqrt{h_{0,t}h_{1,t}}}{h_{0,t}}(r_{0,t} - \mu_0) \\
= \mu_1 + \rho_{1,t}\sqrt{h_{1,t}z_{0,t}}.
\]

The contribution to (minus two times) the log-likelihood function from this conditional density is,

\[
\ell_{z_1|z_0} = \sum_{t=1}^{T} \log[(1 - \rho_{1,t}^2)h_{1,t}] + \frac{(r_{1,t}-\mu_1-\rho_{1,t}\sqrt{h_{1,t}z_{0,t}})^2}{(1 - \rho_{1,t}^2)h_{1,t}}.
\]

The last likelihood term, \( \ell_{u_1,v_1|u_0} \), which relates to the two measurement equations is associated with the conditional density, \( f_{x_1, y_1|r_1, r_0, x_0}(x_{1,t}, y_{1,t}|r_{1,t}, r_{0,t}, x_{0,t}, F_{t-1}) \). First, we note that the conditional distribution of \((u_{1,t}, v_{1,t})\) given \((u_{0,t}, z_{0,t}, z_{1,t})\) is Gaussian with mean

\[
\begin{pmatrix}
\sigma_{u_1,u_0}/\sigma_{u_0}^2 \\
\sigma_{v_1,u_0}/\sigma_{u_0}^2
\end{pmatrix} u_{0,t},
\]

12
and variance
\[ \Omega = \begin{bmatrix} \sigma_{u_1}^2 & \sigma_{u_1,v_1} \\ \sigma_{v_1,u_1} & \sigma_{v_1}^2 \end{bmatrix} - \frac{1}{\sigma_{u_0}^2} \begin{bmatrix} \sigma_{u_0,u_1} & \sigma_{u_0,v_1} \end{bmatrix}. \]

So it does not depend on \((z_{0,t}, z_{1,t})\) due to the assumed independence. The implication is that
\[ f_{x_1,y_1|r_1,r_0,x_0}(x_{1,t}, y_{1,t}|r_{1,t}, r_{0,t}, x_{0,t}, F_{t-1}) = f_{x_1,y_1|r_1,r_0,x_0}(x_{1,t}, y_{1,t}|u_0,t, F_{t-1}), \]
and that the last term in (minus two times) the log-likelihood is given by
\[ \ell_{u_1,v_1|u_0} = \sum_{t=1}^{T} \log \det \Omega + U_{1,t}^\top \Omega^{-1} U_{1,t}, \]
where we have defined
\[ U_{1,t} = \begin{pmatrix} u_{1,t} \\ v_{1,t} \end{pmatrix} - \begin{pmatrix} \sigma_{u_1,u_0}/\sigma_{u_0}^2 \\ \sigma_{v_1,u_0}/\sigma_{u_0}^2 \end{pmatrix} u_{0,t}. \]

The parameters are now estimated by maximizing \( \ell = -\frac{1}{2} (\ell_{z_0} + \ell_{v_0} + \ell_{z_1|z_0} + \ell_{u_1,v_1|u_0}) \).

Fortunately, the structure of this likelihood permits a number of simplifications, which greatly simplify the computational burden in the estimation. These simplifications are detailed in Appendix B.

4 Forecasting

In this section we discuss how multi-step predictions of volatilities and correlations, as well as return density forecasts, can be obtained with our model. Denote \( \tilde{h}_{0,t} \equiv \log h_{0,t}, \tilde{h}_{i,t} \equiv \log h_{i,t} \) and \( \tilde{\rho}_{i,t} \equiv F(\rho_{i,t}). \) Point forecasts turn out to be very easy to obtain owing to the fact that the vector \((\tilde{h}_{0,t}, \tilde{h}_{i,t}, \tilde{\rho}_{i,t})\) can be represented as a VARMA(1,1) system. Substituting each of the measurement equations (5), (8) and (9) into the equations for the corresponding conditional moments and imposing, \( \varphi_0 = 1, \) one obtains
\[
\begin{align*}
\tilde{h}_{0,t+1} &= a_0 + c_0 \xi_0 + (b_0 + c_0 \varphi_0) \tilde{h}_{0,t} + c_0 \delta_0(z_{0,t}) + \tau_0(z_{0,t}) + c_0 u_{0,t} \\
\tilde{h}_{i,t+1} &= a_i + c_i \xi_i + (b_i + c_i \varphi_i) \tilde{h}_{i,t} + d_i \tilde{h}_{0,t+1} + c_i \delta_i(z_{i,t}) + \tau_i(z_{i,t}) + c_i u_{i,t} \\
\tilde{\rho}_{i,t+1} &= a_{i0} + c_{i0} \xi_{i0} + (b_{i0} + c_{i0} \varphi_{i0}) \tilde{\rho}_{i,t} + c_{i0} v_{i,t}.
\end{align*}
\]
Let $V_t = (\tilde{h}_{0,t}, \tilde{h}_{i,t}, \tilde{\rho}_{i,t})'$, then by substituting the equation for $\tilde{h}_{0,t+1}$ into that for $\tilde{h}_{i,t+1}$, one can show that

$$V_{t+1} = C + AV_t + B\varepsilon_t,$$

where $\varepsilon_t = (\delta_0(z_{0,t}), \tau_0(z_{0,t}), \delta_i(z_{i,t}), \tau_i(z_{i,t}), u_{0,t}, u_{i,t}, v_{i,t})'$ and

$$C = \begin{bmatrix} a_0 + c_0\xi_0 \\ a_1 + c_i\xi_i + d_i(a_0 + c_0\xi_0) \\ a_{i0} + c_i0\xi_i \end{bmatrix}, \quad A = \begin{bmatrix} b_0 + c_0\varphi_0 & 0 & 0 \\ d_i(b_0 + c_0\varphi_0) & b_i + c_i\varphi_i & 0 \\ 0 & 0 & b_{i0} + c_0\varphi_i \end{bmatrix},$$

$$B = \begin{bmatrix} c_0 & 1 & 0 & 0 & c_0 & 0 & 0 \\ d_ic_0 & d_i & c_i & 1 & d_ic_0 & c_i & 0 \\ 0 & 0 & 0 & 0 & 0 & c_{i0} & \end{bmatrix}.$$ 

The innovation process, $\varepsilon_t$, is a martingale difference sequence but is slightly heterogeneous, because time-variation in $\rho_{i,t}$ induces time-variation in the distribution of $\varepsilon_t$. It follows that

$$\mathbb{E}(V_{t+k}|V_t) = A^kV_t + \sum_{j=0}^{k-1} A^jC$$

which can be used to produce a $k$-step ahead forecast of $V_{t+k}$.

Forecast of the conditional distribution of $V_{t+k}|\mathcal{F}_t$, which can be used to deduce unbiased forecasts of the non-transformed variables, e.g., $h_{0,t} = \exp(\tilde{h}_{0,t})$, can be obtained by simulation or bootstrap methods. In the simulation approach, we first generate

$$\eta_t := \begin{bmatrix} z_{0,t} \\ \tilde{z}_{i,t} \\ u_{0,t} \\ u_{i,t} \\ v_{i,t} \end{bmatrix} \sim N_5 \left( 0, \begin{bmatrix} I_2 & 0 \\ 0 & \Sigma \end{bmatrix} \right), \quad t = 1, \ldots, N.$$

Given an initialization for $\rho_{i,0}$, one can produce the entire time series $\{\tilde{\rho}_{i,t}\}$ from $\{v_{i,t}\}$ using (10). Next one can define $z_{i,t} = \rho_{i,t}z_{0,t} + \sqrt{1 - \rho_{i,t}^2}w_{i,t}$, which has the proper correlation with $z_{0,t}$, and thus finally $\varepsilon_t$ can be computed. The alternative approach is to bootstrap the residuals, $(\tilde{\eta}_1, \ldots, \tilde{\eta}_N)$, rather than simulating them from the Gaussian distribution. Both approaches were explored in Lunde and Olesen (2013) who produced 1, 5, and 20 days ahead predictions using the Realized Exponential GARCH model. In their application, which used returns on energy forwards, the out-of-sample losses for the two approaches (simulations or bootstrap) were indistinguishable, with either methods being clearly superior to the forecasts produced by
the conventional EGARCH models. In the present context, where the system may be large, the bootstrap approach does have a clear advantage, in that it does not require one to formulate explicit assumptions about the correlation structure of the \( w_{i,t} \)-variables, nor specify the correlation structure of measurement errors across individual assets.

5 Empirical Analysis

5.1 Data Description

The model is estimated for a large cross-section of assets. We included any asset that was a constituent of the S&P 500 index at some point between January 19, 2006 and June 25, 2010, albeit excluding assets for which we had less than 1,000 daily observations during our sample period from January 3, 2002 to the end of 2009. The data were obtained by merging information from the TAQ dataset and the CRSP daily stock files (see Appendix A for further details), and resulted in a total of 594 time series with distinct CRSP Permanent Company Numbers (PERMNOs) and a sample size that ranges from 1,000 to 2,008 observations for each of the individual stocks.

The high-frequency transaction data is cleaned according to the filtering algorithm described in Barndorff-Nielsen et al. (2009), and the multivariate realized kernel by Barndorff-Nielsen et al. (2011) is used as our realized measures of volatility and co-volatility. We use the exchange traded fund, SPY, as a proxy for the market index in our empirical analysis, making the total number of assets in our analysis 595. \(^1\)

5.2 Empirical Results

A summary of the estimation results is presented in Table 1 and Figure 1. \(^2\) The first row in Table 1 contains the estimates for the marginal model for the market return, as defined by equations (3-5), and the rest of the table presents a summary of the estimation results for the 594 conditional models, each defined by equations: (6-9). \(^3\) To conserve space the cross-sectional

\(^1\)The model takes about 3 seconds to estimate for each asset using a workstation (XEON 3.07 GHz) when the simplifications detailed in Appendix B are implemented. The structure is such that the conditional models (one for each individual asset) can be estimated separately, so that one can take advantage of parallel computing.

\(^2\)The results reported are the estimates when imposing the restrictions \( \varphi_i = 1, i = 0, 1, \ldots, N \), which did not result in a significant reduction of the log-likelihood function, see Hansen and Huang (2012) for a discussion on this. The initial values for the latent variables, \( h_{0,t}, h_{i,t} \) and \( \rho_{i,t} \), are treated as unknown parameters.

\(^3\)Note that a row in Table 1 does not present the estimates for a particular stock. For example, the 1% quantile of \( b_0 \) and \( c_0 \) may not be estimates for the same asset.
statistics for the estimates of $\Sigma$ are omitted, but some selected estimates of $\Sigma$ will be presented in Table 2.

Figure 1: Histograms of the 594 parameter estimates for some selected parameters.

The parameter $c_i$, which captures the effect of the lagged realized measure on the conditional variance, is large and significant while the GARCH parameter, $b_i$, is much smaller than is usually the case for conventional GARCH models. The reason is that the realized measure is far more informative about volatility than the squared return, which makes the model far more adaptive to abrupt changes in volatility, which in turn, leads to a better empirical fit and more accurate forecast. The negative estimates of $\tau_{i1}$ and positive estimates of $\tau_{i2}$ indicate the presence of a leverage effect, see Hansen et al. (2012) for the relation of these leverage functions to the news impact curve. Examining the parameters of the measurement equation, we find that $\xi_i$ is negative. This is to be expected because the realized measures are computed over the open-to-close period, which only capture a fraction of daily (close-to-close) volatility. The conditional model for the individual stocks has the additional parameter, $d_i$, in the GARCH equation. This
Table 1: Parameter Estimates of the Realized Beta GARCH Model.

</table>

A summary of the estimated parameters. First row has the estimates from the market return model, (3-5), and information about the cross-section of estimates for the 594 conditional models (6-9) are presented in the remaining rows.
parameter measures the spillover effect from market volatility to individual stock volatility. The mean and the median of this coefficient is positive, and so is the vast majority of the individual estimates. Altogether this shows that market volatility tends to have a positive contemporaneous effect on individual asset volatility.

The cross-sectional variation of parameter estimates are presented in the histogram plots in Figure 1. Both Table 1 and Figure 1 show that the parameter estimates are quite stable in our cross-section of stocks. Only $\hat{\varphi}_{i0}$ is estimated to have an extreme value in some cases, but even in these cases, we have verified that the estimated conditional variances and correlations are in agreement with their corresponding realized measures.

Table 2 presents the estimates of $\Sigma$ for six selected assets. The upper left element in these matrices is the estimated variance of $u_{0,t}$ in the measurement equation for the realized measures associated with the market return. This point estimate varies slightly across the six matrices due to variation in the sample period for the six assets. Note that the measurement error variance for the individual assets tends to be larger than that of the market. This is to be expected because the realized measure for the market return is based on a larger number of high-frequency data. Also note that there is substantial correlation across the measurements error, in particular for the realized measures of volatility.

Table 2: Selected Point Estimates of the Measurement Error Variance.

The estimated measurement error variance matrix, $\Sigma = \text{var}(u_{0,t}, u_{i,t}, v_{i,t})$, for six selected assets, CVX: Chevron; UTX: United Technologies; WMB: Williams Companies; EK: Eastman Kodak; SNV: Synovus Financial; MSFT: Microsoft. The numbers in italic font (upper right triangular) are correlations.

In Figure 2 we present the realized variance of CVX and SPY against the model-implied conditional variance. Clearly, the conditional variance tracks the realized series closely but has less high-frequency variation. Naturally, this relation is largely imposed by the model’s structure, because the measurement equation implies a (noisy) relationship between the conditional
variance and realized measure. The apparent downward bias of the realized measure is due to the fact that it is computed over a fraction of the day (the roughly 6.5 hours where assets are actively traded). This aspect of the realized measures explains why the coefficients $\xi_0$ and $\xi_1$ are negative.

We turn next to the model-implied betas given by

$$\hat{\beta}_t = \hat{\rho}_t \sqrt{\hat{h}_{1,t}/\hat{h}_{0,t}},$$

where $\hat{\rho}_t = \rho_t(\hat{\theta})$ and $\hat{h}_{i,t} = h_{i,t}(\hat{\theta})$, $i = 0, 1$, denote the estimated quantities. The time series can be contrasted to the realized betas

$$\tilde{\beta}_t = y_{1,t} \sqrt{x_{1,t}/x_{0,t}},$$

that are computed exclusively from high-frequency data on day $t$.

The model-implied betas take into account the presence of measurement error in the realized quantities as well as the dynamic linkages between realized measures and conditional moments. To get an idea of the time variation of $\hat{\beta}_t$ in our model compared to its raw realized counterpart,
we continue with our previous example, and present graphic results for the realized and the conditional beta and correlation of CVX in Figure 3. The correlation changes rapidly during the sample period, which carries over to the systematic risk of CVX, as defined by its beta. In fact the beta for CVX ranges from about 0 to more than 1.5 over this period.

In Figure 4 we present quantile time series plots of the cross-sectional variation in the conditional correlation and beta during the financial crisis, where the time of the collapse of Lehman Brothers is clearly identified. It is, perhaps, the period leading up to the collapse of Lehman Brothers that stands out the most. On July 15th the SEC temporarily prohibited naked short selling in the securities of Fannie Mae and Freddie Mac. The time of this announcement coincides with some major changes in the cross-sectional distribution of correlations and betas, although we do not claim any causal relation in this matter. In the subsequent period correlations decreased (on average) and the cross-sectional distribution became increasingly left-skewed. This might suggest that assets became somewhat more susceptible to idiosyncratic shocks and less to market-wide shocks. So it is perhaps surprising that the distribution of conditional betas became more right-skewed. The explanation is that individual asset volatility increased relatively more than market volatility, which more than offset the reduction in average correlation. The mechan-
ics of this is easily understood from the definition of the conditional beta, $\beta_{i,t} = \rho_{i,t}\sqrt{h_{i,t}/h_{0,t}}$.

After this initial chaotic period correlations started to increase and the variation in betas decreased. Eventually, correlations peaked around mid-November with a median value of over 70% well above the 55% value at the beginning of June.

Figure 4: Quantile time series plot of conditional realized GARCH correlations for the period 06.2008 – 12.2009.

It is important to understand that the high degree of variation that we find in the betas should be attributed to variation in the true conditional betas, rather than an artifact of the variation in the realized quantities. The reason is that the variation in the beta produced by the model is driven by features of daily returns. Features that the model attempts to explain to the extent it is possible. From the maximization of the likelihood function it is evident that the realized measures are useful predictors of the covariance structure of daily returns. On the contrary, had there been little variation in the covariance structure of daily returns, then the
likelihood estimation would not produce estimates that caused the realized measures to induce a high degree of variation in the conditional covariance structure. The finding that correlations and betas exhibit a high degree of variation is an important observation. The conventional approach to estimating dynamic betas, typically involve rolling window regression methods using daily returns. This approach induces some degree of smoothing, so it is not surprising that the regression based estimates results in a variation of a much smaller magnitude. Based on rolling window estimated betas of this kind, Lewellen and Nagel (2006) concluded that time variation in beta is insufficient to explain certain asset pricing anomalies. Given the large variation we observed in the systematic risk of individual companies, it could be interesting to revisit this question.

To illustrate the degree of variation in beta, Figure 5 presents the time series of conditional betas for four selected stocks during the second half of 2008. An interesting example is Williams Companies (WMB) that moved from the lower 10% to the upper 10% in the fall of 2008. The example of SNV shows how some financial companies got relatively more risky as the financial crises approached in the early fall of 2008. Finally, we included UTX and EK to show that the
bets of some companies are relatively stable.

5.3 Beta Comparison

An advantage of the Realized Beta model is that it readily produces the time series of the betas, as we illustrated in Figure 5. Similar quantities can be obtained by multivariate GARCH type models that do not utilize realized measures. A prime example of such a model is the Dynamic Conditional Correlation (DCC) model by Engle (2002a).

In this section we compare the betas produced by the Realized Beta GARCH model with those produced by the DCC model as well as a static model that has $\beta$ to be constant. The comparison is done using two methods: First we use a regression-based comparison that was proposed by Engle (2012). Second, we compare the betas using a beta hedging tracking exercise.

The regression-based comparison is based on the auxiliary variables,

$$Z_{i,t}^{RBG} = \hat{\beta}_{i,t}^{RBG} r_{0,t}, \quad Z_{i,t}^{DCC} = \hat{\beta}_{i,t}^{DCC} r_{0,t}, \quad Z_{i,t}^{CAPM} = \hat{\beta}_{i} r_{0,t},$$

and the estimated regression model

$$r_{it} = \alpha + \delta_{i}^{RBG} Z_{i,t}^{RBG} + \delta_{i}^{DCC} Z_{i,t}^{DCC} + \delta_{i}^{CAPM} Z_{i,t}^{CAPM} + \varepsilon_{i,t}, \quad (13)$$

for each of the assets. A specification that yield an ideal time series for $\beta_{it}$ would correspond to its $\delta$-coefficient being one, while the two other $\delta$-coefficients would be zero. Engle (2012) compared the beta of a DCC model to a constant beta using in-sample regressions, and found strong support for the DCC specification. In our comparison, we add the third time series of betas (that of the Realized Beta GARCH model) to the comparison, and make the regression-based comparison using out-of-sample data. This is done as follows: First, we estimated each of the three models using data up until the end of 2007. The estimated models are then used to compute betas out-of-sample from which we construct the auxiliary variables. For the static model, $\hat{\beta}_{i}$ is simply obtained by regressing individual returns on the market return and a constant over the in-sample period.

We estimate (13) by least squares, and test the following three hypotheses

$$H_{RBG} : \delta_{i}^{RBG} = 1, \quad \delta_{i}^{DCC} = \delta_{i}^{CAPM} = 0.$$
\( H_{DCC} : \delta^D_{i} = 1, \delta^RBG_{i} = \delta^CAPM_{i} = 0, \)

\( H_{CAPM} : \delta^CAPM_{i} = 1, \delta^RBG_{i} = \delta^DCC_{i} = 0, \)

using robust inference in the sense of White (1980). In addition, we make a direct comparison between the Realized Beta GARCH model and the DCC model by excluding \( Z_{i,t}^{CAPM} \) from the regression in (13) and test the hypothesis

\( H'_{RBG} : \delta^DCC_{i} = 0 \quad \text{and} \quad H'_{DCC} : \delta^RBG_{i} = 0. \)

Our second comparison of the betas is based on a beta hedging tracking exercise. Here we compute the time series, \((r_{it} - Z_{i,t}^{RBG})\), \((r_{it} - Z_{i,t}^{DCC})\) and \((r_{it} - Z_{i,t}^{CAPM})\) for each asset, and compute their sample variances. In this exercise we seek the one with the smallest variance. For this multiple comparisons problem we apply the Model Confidence Set (MCS) methodology of Hansen et al. (2011), to identify a specification whose variance is significantly smaller than that of the competitors.

The out-of-sample comparison is based on an extended sample that spans four years from the beginning of 2008 to the end of 2011. Our results are based on the 450 assets for which we had data for the full sample period (in-sample as well as out-of-sample).

Panel B: Rejection frequencies

- $H_{RBG}$: 0.72
- $H_{DCC}$: 0.94
- $H_{CAPM}$: 0.92
- $H'_{RBG}$: 0.40
- $H'_{DCC}$: 0.95

Panel C: Frequency in Model Confidence Set

- RBG: 0.88
- DCC: 0.53
- CAPM: 0.45

Comparisons of the betas of the RBG, the DCC, and the CAPM models. Panel A presents summary statistics of the estimated regression coefficients in (13) and four submodels (one that excludes $Z_{i,t}^{CAPM}$ and the three models that only includes one of three regressors. The rejection frequencies for five hypotheses are given in Panel B, and Panel C reports the frequency (across assets) that each of the models are included in the MCS in the beta hedging exercise.

The results are summarized in Table 3. Panels A and B are results from the regression-based comparisons, and Panel C are MCS results from the beta hedging tracing exercise. Panel A presents the average estimated $\delta$-coefficients, from the regression (13), and four subset regressions, also with statistics that summarizes the cross-sectional variation in these estimates, across the 450 assets. The beta deduced from the Realized beta model has, on average, the largest weight. In the regressions using the three auxiliary variables, the DCC models gets little weight. In fact the average coefficient is much smaller than that of the CAPM model, even though the DCC is better than the CAPM in a direct comparison, see Engle (2012). This is explained by a crowding-out effect that occurs when the RBG regressor is included in the analysis. The middle part of Panel A has the estimates from the direct comparison of the RBG and DCC betas, that also points to the RBG betas as being superior to those of the DCC. This is confirmed in the results for the hypotheses tests given in Panel B. The hypotheses that the DCC or the CAPM produce ideal betas, $H_{DCC}$ and $H_{CAPM}$, are almost always rejected. The hypothesis that the
RBG model produce ideal betas, $H_{RBG}$ is also rejected in the majority of cases, but cannot be rejected for 28% of the assets. In the direct comparison between RBG and DCC we reject the $H'_{DCC}$ for the vast majority of assets, however, $H'_{RBG}$ cannot be rejected for 60% of the assets. Thus, for 60% of the assets there is no significant evidence that $\hat{\beta}^{DCC}_{i,t}r_{0,t}$ can explain variation in $r_{i,t}$, that is not already explained by $\hat{\beta}^{RBG}_{i,t}r_{0,t}$.

The general conclusion is further corroborated by the results in Panel C. Here we report the frequency (across assets) by which the tracking error associated with each of the betas is in 90% MCS. The MCS is constructed such that it contains the competitor with the smallest tracking error with a probability no less than 90%. The DCC is found to be significantly inferior for 47% of the assets, and the CAPM is significantly inferior for 55% of the assets. Again, the RBG does better, and there are only 12% of the assets for which the RBG is found to be significantly inferior, which is only slightly more than can be attributed to Type 1 error.

5.4 Residual Correlations and Test for Constant Correlations

The Realized Beta GARCH model implies that the correlation between the individual studentized returns, $z_{it}$ and $z_{jt}$, is time varying. Recall the decomposition

$$z_{i,t} = \rho_{i,t}z_{0,t} + z_{i,t} - \rho_{i,t}z_{0,t} = \rho_{i,t}z_{0,t} + \sqrt{1 - \rho_{i,t}^2}w_{i,t},$$

where $w_{i,t}$ and $z_{0,t}$ are uncorrelated, both have mean zero and unit variance, and in the likelihood analysis we modeled both as standard Gaussian random variables. It follows that

$$\text{corr}(z_{i,t}, z_{j,t}) = \rho_{i,t}\rho_{j,t} + \sqrt{(1 - \rho_{i,t}^2)(1 - \rho_{j,t}^2)}E(w_{i,t}w_{j,t}),$$

which is time varying unless $E(w_{i,t}w_{j,t})$ behaves in a rather unlikely way that offsets the variation in $\rho_{i,t}$ and $\rho_{j,t}$. We have not stated explicit assumptions about the correlation, $E(w_{i,t}w_{j,t})$, which induces additional dependence between $z_{i,t}$ and $z_{j,t}$, beyond that inherited from their correlations with the market return. This additional channel for dependence is ignored in our estimation (in order to make the estimation of large systems feasible). A non-zero correlation between $w_{i,t}$ and $w_{j,t}$ is evidence that the Realized Beta GARCH model does not fully characterize the complete system, so that the estimated model will need to be enhanced to capture such effects. It would also suggest that the estimation is inefficient to some extent, albeit this is to be expected with a relatively simple estimation procedure in a highly complex model.
In this section we study the magnitude of $E(w_{i,t}w_{j,t})$ and the potential evidence of time-variation in this correlations. Since our model implies time variation in the correlation between $z_{i,t}$ and $z_{j,t}$ we shall evaluate the empirical evidence of this.

First, we consider a test for constant correlation that is based on the general theory by Nyblom (1989). This is the underlying framework of several test for parameter constancy including that of Hansen (1992) (linear regression models) and that of Hansen and Johansen (1999) (cointegration VAR).

Consider a bivariate process $(x_t, y_t)$ of studentized variables, $E(x_t) = E(y_t) = 0$ and $E(x_t^2) = E(y_t^2) = 1$; so that the correlation is given by

$$\rho_t = E(x_t y_t).$$

We are to construct tests for constant correlation and zero correlation. The maintained hypothesis is that the partial sum

$$W_T(u) \equiv T^{-\frac{1}{2}} \sum_{s=1}^{[uT]} (x_s y_s - \bar{\rho}), \quad u \in [0, 1],$$

satisfies a functional central limit theorem, so that $W_T(u) \Rightarrow \sigma_W B(u)$ where $B(u)$ is a standard Brownian motion, and $\sigma^2_W$ is the long-run variance of $x_t y_t - \rho_t$.

Under the null hypothesis, $H_0 : \rho_t = \rho$ (constant correlation) it follows that

$$NB_c = \frac{T^{-1} \sum_{t=1}^{T} (T^{-1/2} \sum_{s=1}^{t} (x_s y_s - \bar{\rho}))^2}{\sigma^2_W} \xrightarrow{d} \int_0^1 B_b(u)^2 du,$$

where $B_b(u) = B(u) - uB(1)$ is a standard Brownian bridge, $\bar{\rho} = T^{-1} \sum_{t=1}^{T} x_t y_t$ and $\sigma^2_W$ is some consistent estimator of $\sigma^2_W$. Under the null hypothesis $H_0 : \rho_t = 0$ (zero correlation) we have

$$NB_0 = \frac{T^{-1} \sum_{t=1}^{T} (T^{-1/2} \sum_{s=1}^{t} x_s y_s)^2}{\sigma^2_W} \xrightarrow{d} \int_0^1 B(u)^2 du,$$

where $\sigma^2_W \xrightarrow{p} \sigma^2_{W^*}$. In the absence of serial dependence we can use the estimator $\hat{\sigma}^2_W = T^{-1} \sum_{t=1}^{T} (x_t y_t - \bar{\rho})^2$, which is consistent for $\sigma^2_W$ under both null hypotheses. The 5% critical values of these limit distributions are 0.462 and 1.656, respectively, see Nyblom (1989).

In our application we shall apply the test for constant correlation to $z_{i,t} z_{j,t}$ and $w_{i,t} w_{j,t}$, and the test for zero correlation to $w_{i,t} w_{j,t}$.
With 594 stocks in our cross-section there are 176,121 distinct correlation series to consider. In order to make the presentation manageable, we aggregate the results by industrial segmentation, based on the Global Industry Classification Standard (GICS). The 10 sectors are listed in Table 4 along with the number of companies and summary statistics for their betas within each of the sectors.

</table>

The table gives summary statistics of the sectoral aggregation. The third to fifth columns give the time series average of the minimum, median and maximum beta for each sector. Standard deviations are given in parenthesis.

Next we turn to the constancy of correlations within and across sectors. These results are presented in Tables 5-7. Table 5 gives the sample average of the unconditional correlations for residuals sorted by GICS. The upper panel is for the studentized returns, \( \hat{z}_{i,t} \) and \( \hat{z}_{j,t} \), and serve as a benchmark measure. It is interesting to compare these correlations with those in the lower panel that are based on \( \hat{w}_{i,t} \) and \( \hat{w}_{j,t} \). The differences reveal how much of the correlations between individual stocks that can be attributed to the market factor. The average correlation across \( \hat{w} \)-variables is small for stocks in different sectors, which suggests that the market may account for much of these correlations. However, for stocks within the same sector there is a substantial amount of unexplained correlation, as is evident from the diagonal entries in the lower panel. Thus additional factor (beyond the market factor) is needed to explain the correlation structure of stocks within the same sector. For now we will simply investigate some statistical properties of the residual co-variation and leave the modeling for future work.

Average sample correlations for residuals sorted by industry classification (GICS). Upper panel is for $\hat{z}_{i,t}$ and $\hat{z}_{j,t}$ and the numbers in the lower panel are based on $\hat{w}_{i,t}$ and $\hat{w}_{j,t}$.

In Table 6 we apply the $NB_c$ test for constant correlation to our residual series. We report the rejection frequencies for a 5% significance level. In the upper panel we present the frequencies for the product of the studentized returns, $\hat{z}_{i,t}\hat{z}_{j,t}$. For example, in the case of the 46 energy companies there are 1,035 tests and the null hypothesis of constant correlation is rejected for almost 65% of these test. Once we account for the market factor, and test the hypothesis of constant correlation for the idiosyncratic studentized returns, $w_{it}$, the rejection frequencies are
much smaller, as can be seen from the lower panel of Table 6. This is especially true for assets in different sectors. For stocks within the same sector there continues to be substantial evidence of non-constant correlations, and the same is the case when one (or both) of the assets belongs to the energy sector.

One key message to take away from Table 6 is that the evidence of time-varying correlations

Rejection frequencies for the NB\(_0\) test for zero correlation applied to \(\hat{\omega}_{i,t}\hat{\omega}_{j,t}\).

Table 7 presents the tests for zero correlation. The table reports the rejection frequencies for the \(NB_0\) test applied to the \(\hat{\omega}_{i,t}\hat{\omega}_{j,t}\) series. Given the results in Table 6 it is not surprising that the test is frequently rejected for assets belonging in the same sector. Across sectors the zero-correlation is also frequently rejected. By introducing sector specific factors it may be possible to explain the correlation structure of stocks within the same sector. Since additional factors would change the definition of the residual studentized returns, it is also plausible that sector specific factors could mitigate the residual correlation we find for assets in different sectors. We shall pursue this issue in future research.

6 Conclusion

In this paper we propose a multivariate GARCH model that utilizes realized measures of volatility and correlation, and entails a complete modeling of their dynamic properties. The model builds on a self-contained system of equations that link realized measures to the appropriate population quantities of volatility. The structure implies a dynamic model of the conditional
betas that are popular measures of risk in finance. The proposed framework allows for leverage effects and spillover effects between the assets and the market volatility. In this respect the model combines the flexibility of the GARCH modeling framework with the statistical precision in volatility measurement resulting from the use of high-frequency data. Importantly, the Realized Beta GARCH model has a hierarchical structure that makes it easy to apply to a vast number of assets.

Our empirical study revealed some interesting features of the cross-sectional variation of the conditional betas, as well as their time-series variation. In particular, we find that the betas exhibit substantial variation at a daily frequency – variation that is largely concealed in the rolling-window estimates of $\beta$ that one can obtain with regression methods using daily returns. In our empirical analysis we also found that the Realized Beta GARCH model explains a great deal of the time variation in the correlation structure, and in a comparison of the dynamic betas of the model, with betas of alternative models, we found the betas of the Realized Beta GARCH to have best empirical properties, on average.

Despite the advances brought by the Realized Beta GARCH model, it does not capture all of the dynamics of the large system. This was evident from some Nyblom tests that revealed variation in the correlation structure that could be explained by the underlying market factor. This was particularly the case for correlations between assets that belong to the same sector. For this reason, it will be interesting to consider a generalized structure where additional sector specific correlation factors are used. We shall pursue this generalization in future research.

### A Data

#### A.1 Ticker Symbol and PERMNO

Our data were constructed by merging information from the TAQ dataset and the CRSP daily stock files that were accessed through the WRDS research service. The former provides the high-frequency data used for our construction of realized measures of volatility, and the latter has the
opening and closing prices that are properly adjusted for stock splits and dividends. The TAQ database uses ticker symbols as stock identifiers which can be problematic for a comprehensive analysis such as this one. The reason is that about 10% of the companies in our sample have traded under different ticker symbols during the sample period and, more importantly, some ticker symbols represent very different companies at different points in time. Relying on tickers as identifiers can result in data for two or more companies being mixed up. The CRSP data identifies companies using the CRSP Permanent Company Numbers (PERMNOs) and we can use these to track changes in companies’ ticker symbol, thus ensuring that the proper high-frequency data are extracted from TAQ. This is achieved as follows: First, we match the ticker symbols of the S&P 500 constituents to the CRSP dataset and obtain their PERMNOs. Second, we extract the ticker symbols that were associated with each PERMNO over the sample period. This information is then used to extract high-frequency data from the TAQ, from which our realized measures of volatility are constructed, and the daily data from the CRSP are appended to the time series of realized measures.

A.2 GICS

We employ the sector definition given by the Global Industry Classification Standard (GICS) that is the industry taxonomy developed by Morgan Stanley Capital International (MSCI) and Standard & Poor’s. The GICS structure consists of 10 sectors, 24 industry groups, 68 industries and 154 sub-industries and it is used as a basis for S&P and MSCI financial market indexes. To make our analysis as clear as possible we aggregate to sector level.

To match our stocks to the ten GICS sectors we pair TAQ with Standard & Poor’s CapitalIQ database that contains continuously updated GICS classifications for a large set of publicly listed companies assigned by S&P’s analysts. To match CUSIP and Ticker identifiers from TAQ to the GICS identifiers, TAQ stock identifiers are first matched by CUSIP, and then double checked for a match with company names from CapitalIQ. In cases without a match from this procedure, Ticker’s are used. If this procedure does not provide a match, CapitalIQ Equity Listings report is used to check for inactive listings and these are again matched according to exchange tickers. If none of the above procedures achieve a positive match, CapitalIQ’s business description is used to identify company name changes and a final match is attempted. The above series of matching procedures match all considered TAQ identifiers with available GICS classifications.
B Estimation

B.1 Simplification in Estimation

To simplify the estimation we can concentrate the likelihood function with respect to the covariance matrix of \((u_{0,t}, u_{1,t}, v_{1,t})\). Let \(\hat{u}_{0,t}, \hat{u}_{1,t}\) and \(\hat{v}_{1,t}\) be the residuals of the three measurement equations. The Gaussian likelihood implies that the maximum likelihood estimators of the variance-covariance parameters are given by

\[
\hat{\sigma}^2_{u_0} = \frac{1}{T} \sum_{t=1}^{T} \hat{u}_{0,t}^2, \quad \hat{\sigma}_{u_1,u_0} = \frac{1}{T} \sum_{t=1}^{T} \hat{u}_{1,t} \hat{u}_{0,t}, \quad \hat{\sigma}_{v_1,u_0} = \frac{1}{T} \sum_{t=1}^{T} \hat{v}_{1,t} \hat{u}_{0,t},
\]

and

\[
\hat{\Omega} = \frac{1}{T} \sum_{t=1}^{T} \hat{U}_{1,t} \hat{U}_{1,t}' , \quad \text{where} \quad \hat{U}_{1,t} = \left( \begin{array}{c} \hat{u}_{1,t} \\ \hat{v}_{1,t} \end{array} \right) - \left( \frac{\hat{\sigma}_{u_1,u_0}/\hat{\sigma}^2_{u_0}}{\hat{\sigma}_{v_1,u_0}/\hat{\sigma}^2_{u_0}} \right) \hat{u}_{0,t}.
\]

This reduces the number of free parameters that the likelihood has to be maximized over, to \(\theta = (\theta_0', \theta_1')'\), where

\[
\theta_0 = (\mu_0, \omega_0, a_0, b_0, c_0, \tau_{01}, \tau_{02}, \xi_0, \varphi_0, \delta_{01}, \delta_{02}, h_{0,1})', \quad \text{is the vector of (remaining) parameters in the market model, and}
\]

\[
\theta_1 = (\mu_1, \omega_1, a_1, b_1, c_1, d_1, \tau_{11}, \tau_{12}, \xi_1, \varphi_1, \delta_{11}, \delta_{12}, a_{10}, b_{10}, c_{10}, \xi_{10}, \varphi_{10}, h_{1,1}, \rho_{1,1})',
\]

is the vector of (remaining) parameters in the conditional model. Here we follow the convention and treat the initial values for the latent variables, \(h_{0,1}, h_{1,1}, \text{ and } \rho_{1,1}\), as were they unknown parameters.

These parameters are now estimated by maximizing

\[
\ell(\theta) = -\frac{1}{2} \left( \ell_{z_0}(\theta_0) + \ell_{u_0}(\theta_0) + \ell_{z_1|z_0}(\theta_1) + \ell_{u_1,v_1|u_0}(\theta_1) \right),
\]

where \(\ell_{z_0}(\theta_0) = \sum_{t=1}^{T} \log h_{0,t}(\theta_0) + z_{0,t}^2(\theta_0)\), \(\ell_{u_0}(\theta_0) = T[\log \hat{\sigma}^2_{u_0}(\theta_0) + 1]\), \(\ell_{u_1,v_1|u_0}(\theta) = T[\log \det \hat{\Omega}(\theta) + 2]\), and

\[
\ell_{z_1|z_0}(\theta) = \left( \sum_{t=1}^{T} \log \left[ 1 - \rho^2_{1,t}(h_{1,t}(\theta)) \right] + \frac{(z_{1,t}(\theta) - \rho_{1,t}(\theta) z_{0,t}(\theta))^2}{1 - \rho^2_{1,t}(\theta)} \right).
\]

In practice this amounts to the following procedure:
1. Given initial values for \( \theta_0 \), the time series for \( z_{0,t} \) and \( h_{0,t} \) are computed iteratively. First, 
\[
z_{0,1} = (r_{0,1} - \mu_0) / \sqrt{h_{0,1}},
\] 
then for \( t = 2, \ldots, T \) we compute
\[
h_{0,t}(\theta_0) = \exp \{ a_0 + b_0 \log h_{0,t-1} + c_0 \log x_{0,t-1} + \tau_0(z_{0,t-1}) \},
\]
and \( z_{0,t}(\theta_0) = \frac{r_{0,t} - \mu_0}{\sqrt{h_{0,t}(\theta_0)}} \). This produces the first term of the log-likelihood function, 
\[
\ell_{z_0}(\theta_0) = \sum_{t=1}^{T} \log h_{0,t}(\theta_0) + z_{0,t}^2(\theta_0).
\]

2. Next, we compute \( u_{0,t}(\theta_0) = \log x_{0,t} - \xi_0 - \varphi_0 \log h_{0,t} - \tau_0(z_{0,t}) \) for \( t = 1, \ldots, T \), which yields the second term of the log-likelihood function, 
\[
\ell_{u_0}(\theta_0) = T [ \log \sigma^2_{u_0}(\theta_0) + 1 ],
\]
where \( \sigma^2_{u_0}(\theta_0) = \frac{1}{T} \sum_{t=1}^{T} u_{0,t}^2(\theta_0) \).

3. Now we turn to the conditional model. We compute \( z_{1,1}(\theta_1) = (r_{1,1} - \mu_1) / \sqrt{h_{1,1}} \) and then
\[
h_{1,t}(\theta_1) = \exp \{ a_1 + b_1 \log h_{1,t-1} + c_1 \log x_{1,t-1} + d_1 \log h_{0,t} + \tau_1(z_{1,t-1}) \},
\]
and \( z_{1,t}(\theta_1) = \frac{r_{1,t} - \mu_1}{\sqrt{h_{1,t}(\theta_1)}} \). The notation above suppress that \( h_{1,t} \), and hence \( z_{1,t} \), depend on the market parameters, \( \theta_0 \) (unless \( d_1 = 0 \)). This is implicit since \( h_{0,t} = h_{0,t}(\theta_0) \) depends on \( \theta_0 \), and a similar dependence on \( \theta_0 \) arises below through \( z_{0,t} \) and \( u_{0,t} \). To make this dependence explicit we shall add the argument, \( m_{\theta_0} \), to the likelihood terms below, which is short for the market variables, \( \{ z_{0,t}(\theta_0), h_{0,t}(\theta_0), u_{0,t}(\theta_0) \} \).

Indepedently of \( h_{1,t} \) and \( z_{1,t} \), we can compute:
\[
\rho_{1,t}(\theta_1) = F^{-1} \{ a_{10} + b_{10} F(\rho_{1,t-1}) + c_{10} F(y_{1,t-1}) \}
\]
recursively, for \( t = 2, \ldots, T \). So the third likelihood term is given by
\[
\ell_{z_{1|z_0}}(\theta_1; m_{\theta_0}) = \sum_{t=1}^{T} \log \{ (1 - \rho_{1,t}^2(\theta_1)) h_{1,t}(\theta_1) \} + \frac{(z_{1,t}(\theta_1) - \rho_{1,t}(\theta_1)z_{0,t})^2}{1 - \rho_{1,t}^2(\theta_1)}.
\]

4. The last step involves the two measurement equations in the conditional model, whose residuals are computed by
\[
u_{1,t}(\theta_1) = \log x_{1,t} - \xi_1 - \varphi_1 \log h_{1,t} - \delta_1(z_{1,t}),
\]
\[
v_{1,t}(\theta_1) = F(y_{1,t}) - \xi_{1,0} - \varphi_{1,0} F(\rho_{1,t}).
\]
Next we get $\sigma_{u_1,u_0}(\theta_1) = T^{-1} \sum_{t=1}^{T} u_{1,t}(\theta_1)u_{0,t}$ and $\sigma_{v_1,u_0}(\theta_1) = T^{-1} \sum_{t=1}^{T} v_{1,t}(\theta_1)u_{0,t}$, that is the sample covariances of the measurement errors (that also depend on $\theta_0$ through $u_{0,t} = u_{0,t}(\theta_0)$). This leads to the last likelihood term,

$$\ell_{u_1,v_1|u_0}(\theta_1; m_{\theta_0}) = T(\log \det \Omega(\theta_1; m_{\theta_0}) + 2),$$

where

$$\Omega(\theta_1; m_{\theta_0}) = \frac{1}{T} \sum_{t=1}^{T} U_{1,t}U'_{1,t},$$

with

$$U_{1,t} = U_{1,t}(\theta_1; m_{\theta_0}) = \left( \begin{array}{c} u_{1,t}(\theta_1) \\ v_{1,t}(\theta_1) \end{array} \right) - \left( \begin{array}{c} \sigma_{u_1,u_0}(\theta_1)/\sigma_{u_0}^2 \\ \sigma_{v_1,u_0}(\theta_1)/\sigma_{u_0}^2 \end{array} \right) u_{0,t}.$$

### B.2 Hierarchical Approach to Estimation of Large Systems

When estimating a large system, it is advantageous to use a two-step procedure that the hierarchical structure is well suited for. First we estimate the market model by maximizing

$$-\frac{1}{2} \left\{ \sum_{t=1}^{T} \log h_{0,t}(\theta_0) + z_{0,t}^2(\theta_0) \right\} + T \left[ \log \left( T^{-1} \sum_{t=1}^{T} u_{0,t}^2(\theta_0) \right) + 1 \right].$$

Then in a second step, where we take $\{(h_{0,t}, z_{0,t}, u_{0,t})\}$ as given, which amount to dropping the argument $m_{\theta_0}$ in the expressions of the previous section (steps 3 and 4), we estimate $\theta_i$ by maximizing

$$-\frac{1}{2} \sum_{t=1}^{T} \log \{(1 - \rho_{i,t}^2(\theta_i))h_{i,t}(\theta_i)\} + \frac{(z_{i,t}(\theta_i) - \rho_{i,t}(\theta_i)z_{0,t})^2}{1 - \rho_{i,t}^2(\theta_i)} + T(\log \det \Omega(\theta_i) + 2),$$

for each of the individual assets, $i = 1, \ldots, N$.
